ABSTRACT

Computer-aided diagnostic (CAD) studies are used for scientific observations for explanation since very long time, but they are extraordinarily powerful to perform completely machine-driven algorithmic analyses for brain magnetic resonance imaging lesions. Structural and purposeful imbalance within the human brain could be reviewed. This imbalance analysis of the brain has terrific importance in an image analysis. In the present work, the imbalance between the two hemispheres is considered as the base for the detection of the tumour. We have segmented the brain into the two halves using thresholding technique, followed by statistical feature extraction for the double authentication of the existence of tumour which proves to be the better approach. The approach also takes into consideration corrections needed for the tilt observed while capturing the MRI.

1. Introduction

In trendy medication practices, medical pictures play a significant role and treated as necessary tools for the patient’s designation and treatment. It is terribly troublesome to mechanically find solely the areas of illness in the medical pictures. It is an awfully troublesome method. Thanks to the extraordinarily massive volumes of the knowledge and extreme quality. Computer-aided designation (CAD) is used as an awfully useful gizmo to modify automatic interpretations of the medical pictures. But, it is established to be astonishingly troublesome to perform absolutely machine-driven algorithmic analyze on lesions, exclusively on the data contained in the pictures. Several analysis techniques are evolved for mechanically recognizing the areas of the brain tumor and lump in human brain. To make powerful the processed systems, it might appear insightful to include information and heuristics of disciplines akin to anatomy and pathology to assist the arrangement depict diagnostic inferences.

The CAD system will offer a precious assessment and accuracy of prior tumor recognition. The system consists of 2 stages. The primary stage involves pre-processing and improvement, whereas within the second stage, characteristics pulling out, characteristic choice, categorization, and performance examination are compared and studied. Pre-processing and enhancement methods are helpful to enhance the detection of the suspicious regions in the MRI. Accessing and researching real medical pictures akin to those of MRI, PET or CT scan could be a terribly advanced task as a result of confidentiality problems as well as significant methodological hurdles.

Nowadays, tomography systems square measure vital in medical image process and analysis.

The sample MRI Images are as shown below in figure 1. Depending upon the relaxation times of the fields applied while capturing the MRI of the patients, there are three types T1 weighted, T2 weighted and Flair.
According to radiologic appearance of Tumours they can be categorized as mentioned in the Table 1. The appearance of the tumor is also differing in T1 and T2 weighted images.

Three Major steps in Patient treatment from research point of view are
1. To examine and verify that a structural abnormality is there or not there.
2. Further to locate and evaluate the extent of any abnormality.
3. To exemplify the irregularity if present.

To perform the above-mentioned steps in Brain Tumor Detection, three basic steps are as shown in figure 2.

To perform these steps many researches have used different techniques. different methods are being used by the researchers for performing tumor identification previously. Some are listed in Table 2.

From the literature survey it has been observed that following challenges exists in the Brain tumor Detection:

1. Precise and reproducible segmentation & Characterization of abnormalities are still a demanding and difficult task

2. Still there is significant room for getting increased automation, applicability and accuracy in the existing methods.

The major Difficulty faced by the researchers in MRI processing is the diversity of the feasible shape, location and picture intensities of a range of nature of tumours. Most of the medical imaging studies and detection square measures included antilepton emission imaging (PET) and computerized axial tomography (CT) scanning. Tomography features a dimensional nature and provides completely different information [4, 5].

The remaining paper is structured like follow; section two demonstrates the brain symmetry and its clinical implications. Section three included the brain midsagittal plane detection techniques developed by researchers. Section four describes the proposed approach of the brain hemisphere separation and also illustrates the simulation results. Section V included conclusion and future of the work.

2. Background

Bilateral symmetry is an important aspect of the biology in the humans. Our outlook exhibits symmetricalness in the organs of our body and very few are available in the symmetrical pair off. The neural structure of the individual brain is split into two hemispheres, split by the inter-hemispheric fissure (IF). Assessments of the two hemispheres and finding of variations have been a subject of interest for several years. Traditional human brains exhibit associate fairly accurate symmetricalness with reference to the inter-hemispheric (longitudinal) fissure bisecting the brain, referred to as the anatomical midsagittal plane (MSP). The right and left lobe structures are similar in nature. Notwithstanding, the two halves of the hemispheres have around indistinguishable anatomical properties. Radiologists routinely utilize symmetry as a standout amongst the most separating highlights in conjunction with different characters, for example, area, neighbor-hood relationship, and shape, to survey variations from the norm in brain pictures. An expert clinician identifies the symmetry axis/plane by looking at a medical image and comparison of the abnormality is done with the healthy side of the brain [7]. Nonetheless, human brains are never flawlessly symmetric. Obsessive brains, specifically, frequently leave radically from reciprocal symmetry. For successful neurotic brain picture arrangement and examination, it is most important to characterize a plane of location that is invariant for the symmetrical and also topsy-turvy cerebrum pictures, and it is also important to create calculations that catch this reference plane vigorously [1]

### 3. Research in brain symmetry determination

The highly symmetrical distribution provides an excellent opportunity for researcher to develop symmetry-aided diagnosis techniques. Many researchers are motivated and have been developing many symmetry integrated methods for brain image analysis. In order to retrieve symmetry information from a brain image, it is crucial to identify the precise location of the brain symmetrical plane. Various strategies have been proposed for the brain symmetry location [7].

In radiological scanning process, the brain images obtained may be disoriented. The examined cerebrum pictures are fairly tilted and misshaped. Tilt and contortion can prompt visual wrong review and frequently yield false clinical elucidation, since cuts of the mind pictures are never concordant with the homologous...
structures inside a similar coronal or hub level. The incline of the head is regularly understood in the tool among the examination technique, nevertheless, is not generally manageable.

Regular tenacities behind these sorts of tilts may incorporate; however, are not restricted to fixed status of patients, the freshness of the experts and imprecision of alignment frameworks. Correcting the incline of the head is relational to rearranging the midsagittal plane (MSP) with the principal point of the image cross-section. The MSP is categorized as the level that finest separates the brain into two portions. It is apparent that the rearrangement of the MSP from the geometrical deception yields more sensible information evaluation either by a human master or a PC program that depends on side of the equator insightful cross-referencing.

Symmetry axis is considered as the best isolating central planar brain picture into two parts in 2-D applications. For identifying, dichotomizing, calculating and applying symmetry in image examination here have been many methodologies proposed in the literature. The representative route for deciding symmetry chopper expect the protest is to approximately grade lengthy so the banner of the hub of least inactivity can be utilized to characterize the symmetry chopper of a 2D planar shape. This is the pivot about which the second snapshot of a thin sheet of material of a similar shape is the littllest. The subtle elements of existing strategies for identifying symmetry planes of cerebrum pictures are classified beneath. It ought to be noticed that for any of these calculations, the Resilience to typical asymmetries is the basic of the achievement of anomalous asymmetry recognition. An essential point is that the asymmetry examination as an apparatus for pathology location can't be accomplished without separating ordinary asymmetries from irregular asymmetries [4].

The major challenges to be considered while symmetry analysis can be:

1. Regular asymmetry in the image signal intensity,
2. Irregular asymmetry in the image signal intensity, e.g. the nearness of tumor.
3. Unwanted signals due to geometrical misalignment;
4. Unwanted signals due to non-homogeneity of the indications, e.g., inclination fields.

The calculation shows an edge-based, cross-connection approach that breaks down the plane fitting issue into revelation of two-dimensional symmetry chopper on each cut, trailed by a vigorous estimation of plane parameters. The calculation's resilience to cerebrum asymmetries, input picture balances and picture commotion is quantitatively assessed. The outcomes noted that the calculation can separate the iMSP from input 3-D pictures with extensive topsy-turvy sores, subjective starting revolution balances, low flag to-commotion proportion or high predisposition field. The iMSP calculation is contrasted and an approach in light of augmentation of shared data enlistment, and is found to show unrivaled execution under antagonistic conditions. At long last, it is likewise observed that no factually critical distinction is found between the midsagittal plane processed by the iMSP calculation that assessed by two prepared neuroradiologists. [1]

A mechanized PC helped with perfect midline estimation framework with two-stages incorporates CT Slice Selection Algorithm (SSA) and Ideal midline identification (IML location) involved in the center of the framework. SSA is utilized to extraordinarily lessen the cut number while the IML discovery is intended to precisely distinguish the IML position and turn edge.

This database available includes 3133 pivot CT scan slices. The images have been acquired crosswise over 70 patients with cases including both gentle and serious Traumatic Brain Injuries (TBI). All the accessible CT examinations have been used in testing the framework's procedures and in the estimation of the perfect midline.

A thorough symmetric position seek is performed in light of the anatomical elements in the discovery. Remembering the finish target to promote the precision of the recognition, a worldwide revolution suspicion is connected to decide the perfect midline by completely considering the association between cuts. Trial consequences of the multi-organize calculation were evaluated on 3313 CT cuts of 70 patients. The exactness of the proposed framework is 96.9%. To use any method for the clinical settings exactness is important. So, this feature makes it practical for use under clinical settings [2].
Pixel esteem-based symmetry investigation comprises of three stages. In the primary stage, DICOM records input are changed over into required RGB and Gray arrangements. In the second stage symmetry remainder exhibit in the Axial human cerebrum MRI is figured with the assistance of another parameter as mean pixel esteem angle. X-ray is apportioned into standard size dim level picture into eight constituent modules. The obtained gray level values are observed with more difference in case of asymmetry and likely to be same with some tolerance for normal cases. The method fails to detect the abnormality located on the center line, in which case the symmetry property is retained. [8]

4. Proposed algorithm and simulation results

The proposed algorithm reads the image from the database. Pre-processing of the image is done using median filter. Then, it divides the 2D MRI images into two halves, i.e. left and right, based on the mutual information present in the image.

Based on the mutual information it is decided which half part to process further. First order and second order statistical features are extracted to authenticate the tumor presence or absence.

Similarly, the algorithm is developed to divide the pre-processed image into six and eight equal parts. Extraction of statistical features of complete image is not ending with the optimum results. Hence to improve the algorithm efficiency, number of subsections is done and then features are extracted. The images used for the experimentation are T2 weighted images. The algorithm is applied on the around 30 MRI images available in the database. [10]
Figure 4. Output of proposed algorithm with axial image divided into two equal parts

Figure 5. Graph of mean of two halves without tumor
From the obtained graphs as shown in above in figure 5, 6 and 7 it has been observed that there is negligible difference in the mean value of left and right half in case of chart plotted for MRI scans of normal patient. When tumor is present in the righthalf part rise in mean value is observed for left part and similar observations are seen for images with tumor in the right half portion which is also reflected in the charts plotted.
Figure 8. Output of proposed algorithm with axial images divided into two six equal parts
Figure 9. Output of proposed algorithm with axial images divided into two eight equal parts
5. Conclusion and future scope

There are many algorithms in the literature working on the principal of symmetry property of brain. The first part of proposed algorithm pre-processes the image to remove artefacts, to correct the orientation if any and filtration etc. Then, divides the 2D MRI images into two halves i.e. left and right. It also considers the tilts occurred during the capturing of MRI images. Further, the decision is done on which half to process further. The statistical first order, second order features can be extracted from selected half. Also, the work is extended to divide the image instead of two into either six or eight parts. The decision of detecting tumor present or not is taken based on the features extracted. It is observed that when the image is divided into six or eight it becomes prominent to detect the presence of the tumor.

The extracted features of brain MRI improve the detection rate of tumor when number of sections is increased. In future, the algorithm can be extended to 3D application to calculate the volume. Also, the algorithm can be extended to the problem were the tumor is lying exactly at the center i.e. on the mid line and symmetrically grown on both the sides.
